

# Active Intent Disambiguation for Shared Autonomy Robots

Deepak E. Gopinath and Brenna D. Argall

**Abstract**—Assistive shared-control robots have the potential to transform the lives of millions of people afflicted with severe motor impairments. The usefulness of shared-control robots typically relies on the underlying autonomy’s ability to infer the user’s needs and intentions, and the ability to do so *unambiguously* is often a limiting factor for providing appropriate assistance confidently and accurately. The contributions of this paper are three-fold. First, we propose a *goal disambiguation* algorithm that enhances the intent inference and assistive capabilities of a shared-control assistive robotic arm. Second, we introduce an *intent inference* algorithm inspired by dynamic field theory that works in tandem with the disambiguation scheme. Third, we present a pilot study with eight subjects to evaluate the efficacy of the disambiguation algorithm. Our results suggest that (a) the disambiguation system is of greater utility for more limited control interfaces and more complex tasks, and (b) subjects demonstrated a wide range of disambiguation request behaviors with the common thread of concentrating requests too early in the execution.

**Index Terms**—Assistive Robotics, Shared Autonomy, Intent Inference, Intent Disambiguation

## I. INTRODUCTION

ASSISTIVE and rehabilitation machines—such as robotic arms and smart wheelchairs—have the potential to transform the lives of millions of people with severe motor impairments [1]. With rapid technological advancements in the domain of robotics these machines have become more capable and complex, and with this complexity the control of these machines has become a greater challenge.

The standard usage of these assistive machines relies on manual teleoperation typically enacted through a control interface such as a joystick. However, the greater the motor impairment of the user, the more limited are the interfaces available for them to use. These interfaces (for example, sip-and-puffs and switch-based head arrays) are low-dimensional, discrete interfaces that can only operate in subsets of the entire control space (referred to as *control modes*). The dimensionality mismatch between the interface and the robot’s controllable degrees-of-freedom (DoF) necessitates the user to switch between control modes during teleoperation and has been shown to add to the cognitive and physical burden and affects task performance negatively [2].

The introduction of *autonomy* to these assistive machines can help to alleviate some of the above-mentioned issues. More specifically, with *shared* autonomy the task responsibility is shared between the user and the underlying autonomy. However, for autonomy to be effective in a shared setting, it needs to have a good idea of the user’s needs and intentions. That is, *intent inference* is critical to ensure appropriate assistance.

In this work we consider use-case scenarios in which the autonomy’s inference of user intent is exclusively informed by the human’s control commands issued via the control interface. While to augment the human-robot system with high-fidelity sensors could be a straightforward approach to enhance the autonomy’s intent inference capabilities in the assistive domain, user satisfaction and comfort is of paramount importance and more sensors quickly can become cumbersome (e.g., if the sensors have to be worn by the user) and expensive. Therefore, for reasons of user adoption and cost, we intentionally design our assistance add-ons to be as invisible and close to the manual system as possible. However, intent inference becomes particularly challenging when the user input is low-dimensional and sparse, as is the case with the more limited interfaces available to those with severe motor impairments. The need for intent (goal) *disambiguation* arises as the autonomy needs to reason about all possible goals before issuing appropriate assistance commands.

Our key insight in this work is that certain user control commands are *more intent expressive* than others and therefore may help the autonomy to improve inference accuracy. More specifically, in this work we investigate how the selection of a subset of the operational control dimensions or modes improves the intent inference and disambiguation capabilities of the robot. The three main contributions of this work are as follows:

- 1) First, we develop a control mode selection algorithm which selects the control mode *for* the user, in which the user-initiated motion will help the autonomy to *maximally disambiguate* human intent by eliciting more *intent expressive* control commands from the human. This is important especially in the domain of assistive robotics wherein the user control commands are typically low-dimensional and sparse due to the inherent limitations of the control interfaces.
- 2) Second, as the disambiguation power of our algorithm is closely linked to the fidelity of the underlying intent inference mechanism, we also propose a novel intent inference scheme based on ideas from *dynamic field theory* in which the time-evolution of the distribution over goals is specified as continuous-time constrained dynamical system.

Deepak E. Gopinath is with the Department of Mechanical Engineering, Northwestern University, Evanston, IL and the Shirley Ryan AbilityLab, Chicago, IL.

Brenna D. Argall is with the Departments of Mechanical Engineering, Computer Science and Physical Medicine and Rehabilitation, Northwestern University, Evanston, IL, and the Shirley Ryan AbilityLab, Chicago, IL.

Manuscript received December 2, 2018

- 3) Third, we present results from a pilot study conducted to evaluate the efficacy of the disambiguation algorithm.

In Section II we present an overview of relevant research in the areas of shared autonomy in assistive robotics, shared autonomy assistance paradigms and intent inference and synergies in human-robot interaction. Section III presents our mathematical formalism developed for intent disambiguation and inference. The study design and experimental methods are discussed in Section V followed by results in Section VI. Discussion and conclusions are presented in Sections VII and VIII.

## II. RELATED WORK

This section provides an overview of related research in the domains of shared autonomy in assistive robotics, intent inference in human-robot interaction and information acquisition in robotics.

Shared-autonomy in assistive systems aims to reduce the user's cognitive and physical burden during task execution, typically without having the user relinquish complete control [3], [4], [5], [6]. In order to offset the drop in task performance due to shifting focus (task switching) from the task at hand to switching between different control modes, various mode switch assistance paradigms have been proposed. For example, a simple time-optimal mode switching scheme has shown to improve task performance [2], [7].

Shared control systems often require a good estimate of the human's intent—for example, their intended reaching target in a manipulation task or a target goal location in a navigation task [8]. Intent can be explicitly communicated by the user [9] via various modalities such as laser pointers, click interfaces and in some cases natural language. Intent can also be inferred from the user's control signals and other environmental cues using various algorithms. Within the context of shared autonomy a Bayesian scheme for user intent prediction models the user within the Markov Decision Process framework [10], [11], [12] and is typically assumed to be noisily optimizing some cost function for their intended goal. In low-dimensional spaces, this cost function can be learned from expert demonstrations using Inverse Reinforcement Learning [13].

For high-dimensional spaces, such as that of robotic manipulation, learning cost functions that generalize well over the entire space requires large number of samples. In such cases, heuristic cost functions, such as sum of squared velocities along a trajectory, have been found to be useful for goal prediction [14]. Simple heuristic approaches can also be used to find direct mappings from instantaneous cues and the underlying human intention. Heuristic approaches can incorporate domain-specific knowledge easily and are computationally inexpensive, though the trade-off of this simplicity is not being sophisticated enough to incorporate histories of states and actions, making them less robust to external noise. *Instantaneous* confidence functions for estimating the intended reaching target are employed with success on multiple robotic manipulation systems [15], [5]. In our work we develop an inference algorithm that updates the belief over goals using ideas from dynamic field theory in which the histories of states

and actions are incorporated using a single time-scale parameter and robustness to noise is ensured via recurrent self-interactions that stabilizes the dynamical system.

From the robot's perspective, the core idea behind our intent disambiguation system is that of “*Help Me, Help You*”—that is, if the user can help the robot with more intent-expressive actions, then the robot in turn can provide accurate and appropriate task assistance more accurately and confidently. Related works includes a framework for “*people helping robots helping people*” in which the robot relies on semantic information and judgments provided by the human to improve its own capabilities in [16]. More intent-expressive human actions also is related to the idea of legibility in robot actions. In human-robot interaction, the legibility and predictability of robot motion *to* the human is investigated [17] with various techniques to generate legible robot motion proposed [18]. Our work relies on the idea of *inverse legibility* [19] in which the assistance scheme is intended to bring out more legible intent-expressive control commands *from* the human.

## III. MATHEMATICAL FORMALISM FOR INTENT DISAMBIGUATION

This section describes our intent disambiguation algorithm, that computes the control mode that can maximally disambiguate between the goals, and our intent inference mechanism that works in conjunction with disambiguation algorithm.

### A. Notation

Let  $\mathcal{G}$  denote the set of all candidate goals with  $n_g = |\mathcal{G}|$  and let  $g^i$  refer to the  $i^{th}$  goal with  $i \in [1, 2, \dots, n_g]$ . A *goal* in this context represents the human's underlying intent. Specifically, in assistive robotic manipulation, since the robotic device first must reach toward and grasp discrete objects in the environment, intent inference is the estimation of the probability distribution over all possible discrete goals (objects) in the environment. At any time  $t$ , the autonomy maintains a probability distribution over goals denoted by  $\mathbf{p}(t)$  such that  $\mathbf{p}(t) = [p^1(t), p^2(t), \dots, p^{n_g}(t)]^T$  where  $p^i(t)$  denotes the probability associated with goal  $g^i$ . The probability  $p^i(t)$  represents the robot's confidence that goal  $g^i$  is the human's intended goal.

Let  $\mathcal{K}$  be the set of all controllable dimensions of the robot and  $k^i$  represent the  $i^{th}$  control dimension where  $i \in [1, 2, \dots, n_k]$  with  $n_k = |\mathcal{K}|$ . The limitations of the control interface necessitates  $\mathcal{K}$  to be partitioned into control modes. Let  $\mathcal{M}$  denote the set of all control modes with  $n_m = |\mathcal{M}|$ . Additionally, let  $m^i$  refer to the  $i^{th}$  control mode where  $i \in [1, 2, \dots, n_m]$ . Each control mode  $m^i$  is a subset of  $\mathcal{K}$  such that  $\bigcup_{i=1}^{n_m} m^i$  spans all of the controllable dimensions. A dimension  $k \in \mathcal{K}$  can be an element of multiple control modes.

In this work, we assume a kinematic model for the robot and the kinematic state (the robot's end-effector pose) at any time  $t$  is denoted as  $\mathbf{x}_r(t) \in \mathbb{R}^3 \times \mathbb{S}^3$  and consists of a position and orientation component, where  $\mathbb{S}^3$  is the space of all unit quaternions. The pose for goal  $g \in \mathcal{G}$  is denoted as  $\mathbf{x}_g \in \mathbb{R}^3 \times \mathbb{S}^3$ . The control command issued by the human via

the control interface is denoted as  $\mathbf{u}_h$  and is mapped to the Cartesian velocity of the robot's end-effector. For a 6-DoF robotic arm,  $\mathbf{u}_h \in \mathbb{R}^6$ . The autonomous robot control policy that generates a robot control command is denoted as  $\mathbf{u}_r \in \mathbb{R}^6$ . The control command issued to the robot, which is a synthesis of  $\mathbf{u}_h$  and  $\mathbf{u}_r$  is denoted as  $\mathbf{u} \in \mathbb{R}^6$ . The control command that corresponds to a unit velocity vector along the positive and negative directions of control dimension  $k$  is denoted as  $\mathbf{e}^k$  and  $-\mathbf{e}^k$  respectively.

### B. Disambiguation Metric

The disambiguation metric that we develop in this paper is a *heuristic* measure that characterizes the intent disambiguation capabilities of a control dimension  $k \in \mathcal{K}$  and is denoted as  $D_k \in \mathbb{R}$ . We explicitly define disambiguation metrics for both positive and negative motions along  $k$  as  $D_k^+$  and  $D_k^-$  respectively. We also define a disambiguation metric  $D_m \in \mathbb{R}$  for each control mode  $m \in \mathcal{M}$ . By virtue of design, the disambiguation metric  $D_m$  is a measure of how useful the user control commands would be for the robot to perform more accurate intent inference if the user were to operate the robot in control mode  $m$ . Both  $D_k$  and  $D_m$  will be formally defined in Section III-D. Our computation of  $D_k$  depends on four features (denoted as  $\Gamma_k$ ,  $\Omega_k$ ,  $\Lambda_k$  and  $\Upsilon_k$ ), that capture different aspects of the *shape* of a projection of the probability distribution over intent. These projections and computations are described in detail in Section III-C and Section III-D, and as pseudocode in Algorithm 1.

### C. Forward Projection of $\mathbf{p}(t)$

The first step towards the computation of  $D_k$  is model-based forward projection of the probability distribution  $\mathbf{p}(t)$  from the current time  $t_a$  to  $t_b$  and  $t_c$  (Algorithm 1, lines 4-5) where  $t_a < t_b < t_c$ . We consider two future times in order to compute short-term ( $t_b$ ) and long-term ( $t_c$ ) evolutions of the probability distribution. Application of  $\mathbf{e}^k$  results in probability distributions  $\mathbf{p}_k^+(t_b)$ ,  $\mathbf{p}_k^+(t_c)$  and  $-\mathbf{e}^k$  results in  $\mathbf{p}_k^-(t_b)$  and  $\mathbf{p}_k^-(t_c)$ , where the subscript  $k$  captures the fact that the projection is the result of the application of a control command only along control dimension  $k$ . All parameters which affect the computation of  $\mathbf{p}(t)$  are denoted as  $\Theta$ .

### D. Features of $D_k$

To compute our disambiguation metric, we design four features that encode different aspects of the *shape* of the probability distribution as it evolves under user control in a specific control dimension  $k$ . For each control dimension  $k$ , each of the four features is computed for projections along both positive and negative directions independently. The four features are computed in lines 7 and 10 in Algorithm 1.

1) *Maximum*: The maximum of the projected probability distribution  $\mathbf{p}_k(t_b)$  is a good measure of the robot's *overall certainty* in accurately predicting human intent. We define the distribution maximum as

$$\Gamma_k = \max_{1 \leq i \leq n_g} p_k^i(t_b) \quad (1)$$

### Algorithm 1 Intent Disambiguation

---

**Require:**  $\mathbf{p}(t_a), \mathbf{x}_r(t_a), \Delta t, t_a < t_b < t_c, \Theta$

```

1: for  $k = 0 \dots n_k$  do
2:   Initialize  $D_k = 0, t = t_a, \mathbf{u}_h = \mathbf{e}^k$ 
3:   while  $t \leq t_c$  do
4:      $\mathbf{p}_k(t + \Delta t) \leftarrow \text{UpdateIntent}(\mathbf{p}_k(t), \mathbf{u}_h; \Theta)$ 
5:      $\mathbf{x}_r(t + \Delta t) \leftarrow \text{SimulateKinematics}(\mathbf{x}_r(t), \mathbf{u}_h)$ 
6:     if  $t = t_b$  then
7:       Compute  $\Gamma_k, \Omega_k, \Lambda_k$ 
8:     end if
9:     if  $t = t_c$  then
10:      Compute  $\Upsilon_k$ 
11:    end if
12:     $t \leftarrow t + \Delta t$ 
13:  end while
14:  Compute  $D_k$ 
15: end for
```

---

(i.e., the mode of this discrete distribution). A higher value implies that the robot has a greater confidence in its prediction of the human's intended goal.

2) *Pairwise separation*: More generally, disambiguation accuracy benefits from a larger separation,  $\Lambda_k$ , between goal probabilities. The quantity  $\Lambda_k$  is computed as the *sum of the pairwise distances* between the  $n_g$  probabilities.

$$\Lambda_k = \sum_{i=1}^{n_g} \sum_{j=i}^{n_g} |p_k^i(t_b) - p_k^j(t_b)| \quad (2)$$

$\Lambda_k$  is particularly helpful if the difference between the largest probabilities fails to disambiguate.

3) *Difference between maxima*: Disambiguation accuracy benefits from greater differences between the first and second most probable goals. This difference is denoted as

$$\Omega_k = \max(\mathbf{p}_k(t_b)) - \max(\mathbf{p}_k(t_b) \setminus \max(\mathbf{p}_k(t_b))) \quad (3)$$

$\Omega_k$  becomes particularly important when the distribution has multiple modes and a single measure of maximal certainty ( $\Gamma_k$ ) alone is not sufficient for successful disambiguation.

4) *Gradients*:  $\Gamma_k, \Omega_k$  and  $\Lambda_k$  are local measures that encode shape characteristics of the short-term temporal projections of the probability distribution over goals. However, the quantity  $\mathbf{p}_k(t)$  can undergo significant changes upon long-term continuation of motion along control dimension  $k$ . The spatial gradient of  $\mathbf{p}_k(t)$  encodes this propensity for change and is approximated by

$$\frac{\partial \mathbf{p}_k(t)}{\partial x_k} \simeq \frac{\mathbf{p}_k(t_c) - \mathbf{p}_k(t_b)}{x_k(t_c) - x_k(t_b)}$$

where  $x_k$  is the component of robot's projected displacement along control dimension  $k$ . The greater the difference between individual spatial gradients, the greater will the probabilities deviate from each other, thereby helping in disambiguation. In order to quantify the "spread" of gradients we define  $\Upsilon_k$  as

$$\Upsilon_k = \sum_{i=1}^{n_g} \sum_{j=i}^{n_g} \left| \frac{\partial p_k^i(t)}{\partial x_k} - \frac{\partial p_k^j(t)}{\partial x_k} \right| \quad (4)$$

where  $|\cdot|$  denotes the absolute value.

5) *Putting it all together*: The individual features  $\Gamma_k$ ,  $\Omega_k$ ,  $\Lambda_k$  and  $\Upsilon_k$  are combined to compute  $D_k$  in such a way that, by design, higher values of  $D_k$  imply greater disambiguation capability for the control dimension  $k$ . More specifically,

$$D_k = \underbrace{w \cdot (\Gamma_k \cdot \Lambda_k \cdot \Omega_k)}_{\text{short-term}} + \underbrace{(1-w) \cdot \Upsilon_k}_{\text{long-term}} \quad (5)$$

where  $w$  is a task-specific weight that balances the contributions of the short-term and long-term components (in our implementation,  $w$  is empirically set to 0.5). Equation 5 is computed twice, once in each of the positive ( $e^k$ ) and negative directions ( $-e^k$ ) along  $k$ , and the results ( $D_k^+$  and  $D_k^-$ ) are then summed to compute  $D_k$ .

The computation of  $D_k$  is performed for each control dimension  $k \in \mathcal{K}$ . The disambiguation metric  $D_m$  for control mode  $m$  then is calculated as

$$D_m = \sum_{k \in \mathcal{K}} D_k$$

and the control mode with highest disambiguation capability  $m^*$  is given by

$$m^* = \underset{m}{\operatorname{argmax}} D_m$$

while  $k^* = \underset{k}{\operatorname{argmax}} D_k$  gives the control dimension with highest disambiguation capability  $k^*$ . Disambiguation mode  $m^*$  is the mode that the algorithm chooses for the human to better estimate their intent.

#### IV. INTENT INFERENCE

The intent inference approach introduced in this section is inspired by *Dynamic Field Theory* (DFT) in which the time evolution of the probability distribution  $p(t)$  is specified as a dynamical system with constraints. Dynamic neural fields possess unique characteristics that make them ideal candidates for modeling higher-level cognition. First, a peak in the activation field can be *sustained* even in the absence of external input due to the recurrent interaction terms. Second, information from the past can be *preserved* over large time scales quite

easily by tuning the time-scale parameter, thereby endowing the variables with memory. Third, the activation fields are *robust* to disturbance and noise in the external output [20]. As a result, DFT principles have found widespread application in the area of cognitive robotics [21], scene representation [22], object learning and recognition [23], and obstacle avoidance and target reaching behaviors in both humans and robots [24]. In the context of intent inference, the above-mentioned features result in smoother evolution of the belief over goals and avoid discontinuities in inference and can also incorporate information from distant past states quite easily.

We use the framework of dynamic neural fields to specify the time evolution of the probability distribution  $p(t)$ , in which we treat the individual goal probabilities  $p^i(t)$  as constrained dynamical state variables such that  $p^i(t) \in [0, 1]$  and  $\sum_1^{n_g} p^i(t) = 1$ . The time evolution of the probability distribution is given by

$$\begin{aligned} \frac{\partial p(t)}{\partial t} = \frac{1}{\tau} & \left[ -\mathbb{I}_{n_g \times n_g} \cdot p(t) + \underbrace{\frac{1}{n_g} \cdot \mathbb{I}_{n_g}}_{\text{rest state}} \right] \\ & + \underbrace{\lambda_{n_g \times n_g} \cdot \sigma(\xi(u_h; \Theta))}_{\text{excitatory} + \text{inhibitory}} \end{aligned} \quad (6)$$

where  $u_h$  is the human control input and  $\Theta$  represents all other task-relevant features, time-scale parameter  $\tau$  determines the memory capacity,  $\mathbb{I}_{n_g \times n_g}$  is the identity matrix,  $\mathbb{I}_{n_g}$  is a vector of dimension  $n_g$  containing all ones,  $\lambda$  is the control matrix that controls the excitatory and inhibitory aspects,  $\xi$  is a function that encodes the nonlinearity through which human control commands and task features affect the time evolution, and  $\sigma$  is a biased sigmoidal nonlinearity given by  $\sigma(\xi) = \frac{1}{1+e^{-\xi}} - 0.5$ . The key adaptation required to use DFT for intent inference is in the design of  $\xi$ .

Our design of  $\xi$  is informed by what features of the human control input and environment effectively capture the human's underlying intent. We choose the *directedness* of the robot motion towards a goal, the *agreement* between the human commands and robot autonomy, and the *proximity* to a goal. The *directedness* component looks at the shortest straight line path towards a goal  $g$ , whereas the *agreement* serves as an indicator of how close are human and autonomy signals. One dimension  $i$  of  $\xi$  is defined as

$$\begin{aligned} \xi^i(u_h; x_r, x_{g^i}, u_{r,g^i}) = & \underbrace{\frac{1+\eta}{2}}_{\text{directedness}} + \underbrace{u_h^{\text{rot}} \cdot u_{r,g^i}^{\text{rot}}}_{\text{agreement}} \\ & + \underbrace{\max\left(0, 1 - \frac{\|x_{g^i} - x_r\|}{R}\right)}_{\text{proximity}} \end{aligned}$$

where  $\eta = \frac{u_h^{\text{trans}} \cdot (x_{g^i} - x_r)^{\text{trans}}}{\|u_h^{\text{trans}}\| \|(x_{g^i} - x_r)^{\text{trans}}\|}$ ,  $u_{r,g^i}$  is the robot autonomy command for reaching goal  $g^i$ , *trans* and *rot* refer to the translational and rotational components of a command  $u$  or position  $x$ ,  $R$  is the radius of the sphere beyond which the proximity component is always zero,  $\|\cdot\|$  is the Euclidean norm and  $\Theta = \{x_r, x_{g^i}, u_{r,g^i}\}$ . At every time-step constraints on  $p^i(t)$  are enforced such that  $p(t)$  is a valid probability

Fig. 1. Goal inference using our dynamic field theory (DFT) approach (left) and the Bayesian approach (right). Goals shown as circles. The motion trajectory is colored according to the goal prediction made at that location during the execution. The human operator first reaches towards the blue goal, then the red and finally the yellow.

distribution. The most confident goal  $g^*$  is computed as  $g^* = \operatorname{argmax}_i p^i(t)$ .

Figure 1 shows an illustrative comparison of goal inference using our DFT based approach and a Bayesian approach using a distance-based cost function used during shared autonomy operation. We found that, in general, both inference mechanisms consistently produced similar performances (intent prediction correctness) for a wide variety of goal configurations. In order to incorporate history of states, Bayesian approaches have to reason over the entire trajectory which can become computationally expensive, whereas in the DFT approach this is achieved by tuning the time-scale parameter.

## V. STUDY METHODS

In this section, we describe the study methods used to evaluate the efficacy of the disambiguation system.

**Participants:** For this study eight subjects were recruited (mean age:  $31 \pm 11$ , 3 males and 5 females). All participants gave their informed, signed consent to participate in the experiment, which was approved by Northwestern University's Institutional Review Board.

**Hardware:** The experiments were performed using the MICO 6-DoF robotic arm (Kinova Robotics, Canada), specifically designed for assistive purposes. The software system was implemented using the Robot Operating System (ROS) and data analysis was performed in MATLAB. The subjects teleoperated the robot using two different control interfaces: a 2-axis joystick and a switch-based head array, controlling the 6D Cartesian velocities of the end-effector (Figure 2). An external button was provided to request the mode switch assistance.

In detail, the joystick generated 2-D continuous control signals. Under joystick control the full control space was partitioned into five control modes that were accessed via button presses. The switch-based head array consisted of three switches embedded in the headrest, operated via head movements and generated 1-D discrete signals. Under head array control the full control space was partitioned into seven control modes, the back switch was used to cycle between the different control modes, and the switches to the left and right controlled the motion of the robot's end effector in the positive and negative directions along a selected control dimension.

**Tasks:** Two different task types were evaluated.

**Single-step:** The aim was to reach one of five objects on the table, each with a target orientation (Figure 3, Left).

Control Mappings		
Mode	Head Array	Joystick
1	$v_x$	$v_x, v_y$
2	$v_y$	$v_x, v_z$
3	$v_z$	$\omega_z, \omega_y$
4	$\omega_z$	$\omega_x$
5	$\omega_y$	gripper
6	$\omega_x$	—
7	gripper	—

Fig. 2. A 2-axis joystick (left) and switch-based head array (center) and their operational paradigms (right).  $v$  and  $\omega$  indicate the translational and rotational velocities of the end-effector, respectively.

**Multi-step:** Each trial began with a full cup held by the robot gripper. The task required first that the contents of the cup be poured into one of two containers, and then that the cup be placed at one of the two specified locations and with a specific orientation (Figure 3, Right).

**Switching Paradigms:** Two kinds of mode switching paradigms were evaluated in the study.

**Manual:** During task execution the user performed all mode switches.

**Disambiguation:** The user either performed a mode switch manually or requested a switch to a *disambiguation* mode. Disambiguation requests could happen at any time during task execution, upon which the algorithm identified and switched the current control mode to the best disambiguating mode  $m^*$ . The user was required to request disambiguation at least once during the task execution.

**Shared Control:** Autonomy assistance was always active for both disambiguation paradigms. We used a blending-based shared-control paradigm in which the final robot control command was a linear composition of the human control command and an autonomous robot policy. With blending the amount of assistance was directly proportional to the probability of the most confident goal  $g^*$ , and thus to the strength of the intent inference. Therefore, if intent inference improved as a result of goal disambiguation, more assistance would be provided by the robot.

Specifically, the autonomous control policy generates control command  $\mathbf{u}_r \leftarrow f_a(\mathbf{x}_r)$  where  $f_a(\cdot) \in \mathcal{F}_a$ , and  $\mathcal{F}_a$  was the set of all control behaviors corresponding to different tasks. This set could be derived using a variety of techniques such as *Learning from Demonstrations* [25], [26], motion planners [27], [28] or navigation functions [29], [30]. In our implementation, the autonomy's control command was generated using a simple potential field which is defined in all parts of the state space [31]. Every goal  $g$  was associated with a potential field  $\gamma_g$  which treats  $g$  as an attractor and all the other goals in the scene as repellers. The autonomy command was computed as a summation of the attractor and repeller velocities and operated in the full 6D Cartesian space.

Let  $\mathbf{u}_{r,g}$  be the autonomy command associated with goal  $g$ . Under blending, the final control command  $\mathbf{u}$  issued to the robot then was given by

$$\mathbf{u} = \alpha \cdot \mathbf{u}_{r,g^*} + (1 - \alpha) \cdot \mathbf{u}_h$$

where  $g^*$  was the most confident goal. Similar to  $\mathbf{u}_h$ , the autonomy command  $\mathbf{u}_{r,g^*} \in \mathbb{R}^6$  is mapped to the 6D Cartesian velocity of the end-effector. The blending factor  $\alpha$  was a piecewise linear function of the probability  $p(g^*)$  associated with  $g^*$  and was given by

$$\alpha = \begin{cases} 0 & p(g^*) \leq \rho_1 \\ \frac{\rho_3(p(g^*) - \rho_1)}{\rho_2 - \rho_1} & \text{if } \rho_1 < p(g^*) \leq \rho_2 \\ \rho_3 & p(g^*) > \rho_2 \end{cases}$$

with  $\rho_i \in [0, 1] \ \forall \ i \in [1, 2, 3]$  and  $\rho_2 > \rho_1$ . In our implementation, we empirically set  $\rho_1 = \frac{1.2}{n_g}$ ,  $\rho_2 = \frac{1.4}{n_g}$  and  $\rho_3 = 0.7$ .

**Study protocol:** A within-subjects study was conducted using a fractional factorial design in which the manipulated variables

Fig. 3. Study tasks performed by subjects. *Left*: Single-step reaching task. *Right*: Multi-step pouring task.

were the tasks, control interfaces and the switching paradigm conditions. Each subject underwent an initial training period that lasted approximately 30 minutes.

The training period consisted of three phases and two different task configurations. The subjects used both interfaces to perform the training tasks.

**Phase One:** The subjects were asked to perform a simple reaching motion towards a single goal in the scene. This phase was intended for the subjects to get familiarized with the control interface mappings and teleoperation of the robotic arm.

**Phase Two:** In the second phase of training, subjects experienced how the blending-based autonomy provided assistance during task execution.

**Phase Three:** For the third phase of the training, multiple objects were introduced in the scene. Subjects were explicitly informed by the experimenter that upon a disambiguation request the robot would select a control mode that would help the robot figure out which goal the subject was going for and thereby enable it to assist the user more effectively. Subjects were able to explore this request feature during a reaching task, to observe the effects of the mode switch request and subsequent change in robot assistance.

During the testing phase, each subject performed both tasks using both interfaces under the *Manual* and *Disambiguation* paradigms. All trials started in a randomized initial control mode and robot position. The ordering of control interfaces and paradigms was randomized and counterbalanced across all subjects. Three trials were collected for the *Manual* paradigm and five trials for the *Disambiguation* paradigm.

**Metrics:** The objective metrics used for evaluation included the following.

- *Number of mode switches:* The number of times a user switched between various control modes during task execution.
- *Number of disambiguation requests:* The number of times user pressed the disambiguation request button.
- *Number of button presses:* The sum of *Number of mode switches* and *Number of disambiguation requests*, and is also an indirect measure of user effort.
- *Skewness:* A higher-order moment used to quantify the asymmetry of any distribution. Used to characterize how

much the temporal distribution of disambiguation requests deviates from a uniform distribution.

## VI. RESULTS

Here we report the results of our subject study. Our study results indicated that the disambiguation request system is of greater utility for more limited control interfaces and more complex tasks and subjects demonstrated a wide range of disambiguations request behaviors with a common theme of relying on disambiguation assistance early in the trials. Statistical significance was determined by the Wilcoxon Rank-Sum test in where (\*\*\*) indicates  $p < 0.001$ , (\*\*)  $p < 0.01$  and (\*)  $p < 0.05$ .

**Impact of Disambiguation on Task Performance:** A statistically significant decrease in the number of button presses was observed between the *Manual* and *Disambiguation* paradigms when using the headarray (Figure 4, Left). Due to the low-dimensionality of the headarray and cyclical nature of mode switching, the number of button presses required for task completion is inherently high. That the disambiguation paradigm was helpful in reducing the number of button presses likely is due to higher robot assistance in the disambiguating control mode and therefore reduced the need for subsequent user-initiated mode switches. For the joystick, statistically significant

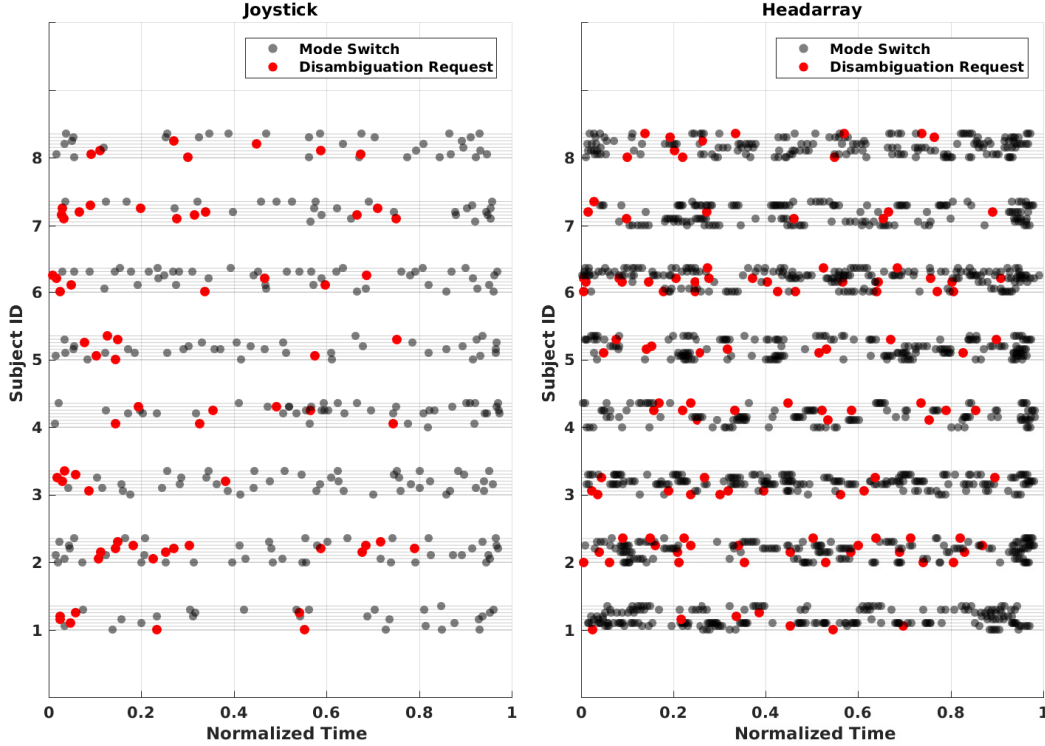

Fig. 5. Temporal pattern of button presses for each interface and the multi-step task on a trial-by-trial basis for all subjects. Eight trials per subject per interface/task combination.

differences between the two paradigms were observed for the number of manual mode switches ( $p < 0.05$ ). However, this gain was offset by the button presses that were required for disambiguation requests. When grouping by task, the general trend (although not statistically significant) of a decrease in the number of button presses was more pronounced for the more complex multi-step task (Figure 4, Right).

These results suggest that disambiguation is more useful as the control interface becomes more limited and the task becomes more complex. Intuitively, intent prediction becomes harder for the robot when the control interface is low-dimensional and does not reveal a great deal about the user's underlying intent. By having the users operate the robot in the disambiguating mode, the robot is able to elicit more intent-expressive control commands from the human which in turn helps in accurate goal inference and subsequently appropriate robot assistance.

**Temporal Distribution of Disambiguation Requests:** The temporal distribution of disambiguation requests refers to *when* the subject requested assistance during the course of a trial. We observed that a higher number of disambiguation requests correlates with the more limited interface and complex task.

From Figure 5 it is clear that the frequency and density of button presses (disambiguation requests plus mode switches) are much higher for the more limited control interface. The subjects also demonstrated a diverse range of disambiguation request behaviors, for example in regards to both when during the execution requests were made and with what frequency (e.g.,

Subject 8 versus Subject 2, Joystick). The variation between subjects is likely due to various factors such as the user's comfort in operating the robot and understanding the ability of the disambiguating mode to recruit more assistance from the autonomy. The skewness of the temporal distribution of disambiguation requests revealed a higher concentration of during the earlier parts of a trial (Table I) for both interfaces and tasks. However, under headarray control the temporal distribution was less skewed as the need for disambiguation request persists throughout the trial due the extremely low-bandwidth of the interface.<sup>1</sup>

## VII. DISCUSSION

The disambiguation algorithm presented in our work can be utilized in any human-robot system in which there is a need to disambiguate between the different states a discrete hidden variable can assume (for example, a discrete set of goals

in robotic manipulation or a set of landmarks in navigation tasks). Our algorithm assumes the existence of a discrete set of parameters (for example, control modes for robotic manipulation or natural language-based queries for navigation) that can help the intent inference mechanism to precisely converge to the correct inference. Although the disambiguation algorithm is task-agnostic—because it relies exclusively on the shape features of the probability distribution over the hidden variable—the disambiguation is only as good as the efficacy of the intent inference algorithm that is used for as specific task. In our experience, it becomes important that the choice of cost functions and domain-specific heuristics is appropriate for the task at hand. The efficacy of the disambiguation algorithm degraded when we used only a subset of the four features to inform the disambiguation metric. This only reinforces the need for a combination of different shape features for successful disambiguation.

One observation from our subject study was how often participants submitted a disambiguation request and then chose not to operate in the selected mode—effectively not letting the robot help them. Our preliminary analysis showed that even though the autonomy was in a control mode that could have helped it perform accurate intent inference and subsequently assist the human, the user was not able to capitalize on it and utilize it to his/her advantage. As a result no differences in the onset of assistance was observed between the two switching paradigms across tasks or across interfaces. This highlights the need for greater transparency in the human-robot interaction, so that the human has a clear picture of *how* and *why* the robot chooses to help the user in certain ways. A lack of understanding of how they might help the robot to help them might have resulted in the under-utilization of the disambiguation feature. In order to provide *intent-expressive* control commands to the robot, very likely knowledge of the assistance mechanism is critical. Therefore, the need for extensive and thorough training becomes apparent. The training can be made more effective in a few different ways. First, online feedback of the robot's intent prediction at all times during training can likely help the subject gain a better understanding of the relationship between the characteristics of their control actions (sparsity, aggressiveness, persistence) and the robot's assistive behavior. Second, the subjects could be explicitly informed of the task relevant features (directedness, proximity *et cetera*) that the robot relies on for determining the amount of assistance. Knowledge of these features might motivate the users to leverage the disambiguating mode.

In the present system, there is task effort associated with requesting disambiguation assistance, which also might discourage the users from utilizing the paradigm. An improvement would be automated mode switching schemes that eliminate the need for button presses for disambiguation requests.

## VIII. CONCLUSION

In this paper, we have presented an algorithm for *intent disambiguation assistance* with a shared-control robotic arm using the notion of *inverse legibility*. The goal of our algorithm is to elicit more *intent-expressive* control commands from the

user by placing control in those control modes that *maximally disambiguate* between the various goals in the scene. As a secondary contribution, we also present a novel intent inference mechanism inspired by *dynamic field theory* that works in conjunction with the disambiguation system. A pilot user study was conducted with eight subjects to evaluate the efficacy of the disambiguation system. Our results indicate a decrease in task effort in terms of the number of button presses when disambiguation system employed.

In our future work, as informed by our pilot study, we plan to extend the framework into an automated mode switch assistance system. A more extensive user study with motor-impaired subjects will also be conducted in the future to further evaluate the utility of the disambiguation system and explore the disambiguation request patterns of users.
